Blurred boundaries: A flexible approach for segmentation applied to the car market

LAURA GRIGOLON
Department of Economics, University of Mannheim, MaCCI, and CEPR

Prominent features of differentiated product markets are segmentation and product proliferation blurring the boundaries between segments. I develop a tractable demand model, the Ordered Nested Logit, which allows for asymmetric substitution between segments. I apply the model to the automobile market where segments are ordered from small to luxury. I find that consumers, when substituting outside their vehicle segment, are more likely to switch to a neighboring segment. Accounting for such asymmetric substitution matters when evaluating the impact of new product introduction or the effect of subsidies on fuel-efficient cars.

Keywords. Discrete choice model, Generalized Extreme Value, Ordered Nested Logit.

JEL classification. D11, D12, L62, M3.

1. Introduction

In most differentiated product markets, products can be partitioned into segments according to shared common features. Segmentation is not only a descriptive process, but also a practice used by firms to develop targeted marketing strategies and decide the placement of their products. Often, segments can be ordered in a natural way. Cars can be ordered from small (subcompact) to luxury according to price, size, engine performance, comfort, and prestige; hotels and restaurants can be ordered on the basis of their ratings (number of stars); retail brands can be ordered in tiers according to quality and price.

In parallel with segmentation, the variety of products has also dramatically increased over time: cars, computers, printers, and smartphones are just a few examples of industries in which product proliferation is visibly prevalent. Broadening the product line has blurred the boundaries between segments, thus decreasing the distance between them: a premium subcompact car can be a potential substitute for a compact car. As a consequence, segments tend to overlap with their neighbors. Correlation between segments has important implications when we want to measure the impact of competitive events.
such as the introduction of varieties combining features from different segments. Environmental policies aimed at encouraging the adoption of cleaner cars can also affect sales across segments differently.

I propose a new discrete choice model, the Ordered Nested Logit model, that captures ordered segmentation in differentiated product markets and allows for asymmetric substitution toward proximate neighbors. This model is a new member of the Generalized Extreme Value (GEV) model family developed by McFadden (1978). I construct the Ordered Nested Logit in the context of market level data. The GEV family is consistent with random utility theory and yields a tractable closed-form for choice probabilities.Berry (1994) has provided a framework to estimate two special members of this family with market level data: the Logit and the Nested Logit model. The Ordered Nested Logit model generalizes the Nested Logit model by incorporating an extra parameter that measures the correlation in preferences between neighboring segments: the Nested Logit model implicitly sets such correlation to zero. Hence, the Ordered Nested Logit has the Nested Logit and the Logit as special cases: it can serve as a test for the validity of the constraints imposed by the Nested Logit and, a fortiori, the Logit model. Apart from these two models, only a few other members of the GEV model family have been exploited so far with market level data: notable examples are the principles of differentiation model by Bresnahan, Stern, and Trajtenberg (1997), the flexible coefficient multinomial logit by Davis and Schiraldi (2014), and the inverse product differentiation logit model by Fosgerau, Monardo, and de Palma (2019).

Is asymmetric substitution toward neighboring segments captured by the demand models we currently use? In the Nested Logit model, neighboring segment effects are ruled out by construction. The model requires the stochastic components of utility attached to the segment choice to be independent. Therefore, while preferences can be correlated across products within the same segment (or nest), substitution outside a segment is symmetric to all other segments. In contrast, the Random Coefficients Logit model by Berry, Levinsohn, and Pakes (1995) has the potential to generate more flexible substitution patterns, where products tend to be closer substitutes as they share similar observed continuous characteristics. Grigolon and Verboven (2014) simulate the effect of a joint 1% price increase of all cars in a given segment and show that the Random Coefficients Logit model yields more intense substitution toward neighboring segments. But flexibility is achieved only if the parameters of the models, which determine how the random coefficients govern substitution patterns, are correctly and precisely identified. Berry and Haile (2014) clarify that the identification of those parameters poses a distinct empirical problem from price endogeneity and provide general results for identification in differentiated product markets, showing that those parameters are identified by standard exclusion restrictions. Reynaert and Verboven (2014) and Gandhi and Houde (2019) study practical instrumentation strategies for empirical work. With market share data, we can only use the mean choice probabilities (the market shares) as moments that identify the parameters measuring heterogeneity. Good instruments would mimic the ideal experiment of random variation in the characteristics or number of products to identify the response in terms of market shares; in practice, identification can prove
difficult in complex set-ups, especially with four or more random coefficients, as documented by Reynaert and Verboven (2014). The Ordered Nested Logit relies on the same variation in the data to identify the nesting and neighboring nesting parameters; by assuming and estimating a correlation structure based on the proximity of product groups, the model can be a parsimonious alternative to the Random Coefficients Logit model. Finally, the Random Coefficients Logit model does not produce a closed form for the choice probabilities. Earlier work documented sources of numerical issues (e.g., Knittel and Metaxoglou (2014)) and recent articles (Kalouptsidi (2012), Dubé, Fox, and Su (2012), Lee and Seo (2015)) have proposed methods that improve the performance of random coefficients models. Berry, Linton, and Pakes (2004) derive the properties of the nested fixed-point estimator and show that the simulation error in the approximation of the market shares is bounded only if the number of draws rises with the sample size. Avoiding the simulation of market shares altogether may alleviate some of those difficulties.

First, I formally derive the Ordered Nested Logit model and relate it to commonly used discrete choice models, focusing on the comparison of substitution patterns implied by the Nested Logit and the Ordered Nested Logit model. Using simulated data, I document the flexibility of the Ordered Nested Logit in producing asymmetric substitution patterns and handling misallocation of products into nests. I also provide guidance on the design of the nesting structure.

Next, I apply the Ordered Nested Logit model to a unique data set on the car market covering three major European countries between 1998 and 2011. The process of purchasing a car is modeled as a nested sequence, with the choice between the segments (including the outside good segment) at the upper node level and the choice of the specific vehicle at the lower node. I estimate the degree of correlation in consumer preferences both within each segment, as in the Nested Logit model, and in neighboring segments. The demand estimates of the Ordered Nested Logit model clearly indicate a rejection of the simpler Nested Logit model: Correlation in car choices is present not only within a segment, but also between neighboring segments.

The demand estimates have striking implications for the substitution patterns. While the Nested Logit model yields symmetric and very low substitution toward other segments, the Ordered Nested Logit model shows a large substitution effect to the neighboring segments. I look at the impact of the introduction of premium subcompact cars on sales by vehicle class. The Nested Logit model predicts that only sales of other subcompact cars are affected by the introduction of those vehicles, while the Ordered Nested Logit model shows, more plausibly, that the segment immediately above (compact cars) is affected as well. Next, I simulate a subsidy to clean vehicles: such policy is clearly asymmetric because it favors mainly subcompact and compact cars. The Nested Logit model predicts again that sales of nonsubsidized cars do not notably change after the policy, while the Ordered Nested Logit model shows a sizeable decrease in sales of

1Brunner et al. (2017) document that the simulation errors in the approximation of the market shares can generate failure to convergence to a local minimum, numerical instabilities, and unreliable identification of the parameters governing the substitution patterns.
the upper segments, especially the standard segment, which has cars that are just above the eligibility threshold.²

1.1 Related literature

The model I propose takes inspiration from the literature on Nested Logit models (Williams (1977); Daly and Zachary (1977); McFadden (1978)) and from the Ordered Generalized Extreme Value (OGEV) model by Small (1987). The OGEV model was the first closed-form GEV model to allow for taste correlation between neighboring products. However, it has been developed in settings where a limited number of alternatives have a natural order so that correlation in unobserved utility between two alternatives depends on their proximity in the ordering. With market level data, such as a data set on the car market, ordering hundreds of products in each market would prove impossible, while ordering groups of products, the segments, is a sensible strategy to obtain a tractable model and flexible substitution patterns. Several other authors have tried to relax the hierarchical structure imposed by the Nested Logit, especially in the transportation literature; see Chu (1989); Vovsha (1997); Ben-Akiva and Bierlaire (1999). The most flexible model in this literature is the generalized Nested Logit model by Wen and Koppelman (2001), where an alternative can be a member of more than one nest to varying degrees. Bresnahan, Stern, and Trajtenberg (1997) develop a principles of differentiation model, which is an example of a closed-form GEV model applied to market-level data. Grigolon and Verboven (2014) show in their empirical application to the car market that sources of market segmentation may not be captured by the continuously measured characteristics in the Random Coefficients Logit model. They do so by adding a nested logit structure to BLP’s random coefficients model. This paper builds on that work by considering a new tractable model from the GEV family to capture an additional feature of such heterogeneity: ordering in market segmentation. The Ordered Nested Logit accounts explicitly for this form of vertical differentiation by estimating a parameter that measures such correlation in preferences between neighboring segments. Davis and Schiraldi (2014) propose an analytic model capable of generating flexible substitution patterns combining elements of the Paired Combinatorial Logit and the Cross Nested Logit. Their model is fully flexible as it can potentially avoid the restrictiveness of Logit and Nested Logit models allowing the second cross derivatives between any pair of goods to be nonzero. In the Ordered Nested Logit, the second cross derivative between pairs of products belonging to different nests and neighboring segments is instead zero. In practice, estimating all the parameters in the model proposed by Davis and Schiraldi (2014) would prove unfeasible, as it is impossible to estimate all alternative specific constants in a Logit model. The authors impose a form of structure to avoid proliferation of parameters that arises with a large number of products: they parametrize the correlation parameters to be the function of the distance between products, following Pinkse,

²Green subsidies are usually temporary and naturally call for a dynamic approach to model consumers’ decisions over time, which can be implemented only with additional information on the secondary market and the patterns of ownership (see Schiraldi (2011)). The Ordered Nested Logit model could also be useful in a dynamic framework, as it avoids the need of simulating the market share integral thus potentially alleviating some numerical difficulties.
Slade, and Brett (2002). In the same spirit, the Ordered Nested Logit explicitly models the idea of varying degrees of distance between nests. Finally, Fosgerau, Monardo, and de Palma (2019) propose an empirical model specified in terms of inverse demand: their model extends the nested logit by allowing segmentation to be nonhierarchical, while maintaining tractability.

The remainder of the article is organized as follows. Section 2 puts forward the Ordered Nested Logit model. A study using simulated data illustrates the flexibility of the model. Section 3 describes the application data set and the econometric procedure, including the identification issues. Section 4 provides the empirical results and the implied price elasticities. Section 5 presents the policy counterfactuals. Section 6 concludes.

2. Modeling correlation between neighboring segments

Demand is modeled within the discrete choice framework. Consider $T$ markets, $t = 1, \ldots, T$, with $L_t$ potential consumers in each market. Markets are assumed to be independent, so I suppress the market subscript $t$ to simplify notation. Each consumer $i$ chooses a specific product $j$, $j = 1, \ldots, J$. Consumer $i$’s indirect utility is

$$U_{ij} = x_j \beta - \alpha p_j + \xi_j + \varepsilon_{ij}$$

$$\equiv \delta_j + \varepsilon_{ij},$$

where $x_j$ is a vector of observed product characteristics, $p_j$ is price, and $\xi_j$ is the unobserved product characteristic. Following Berry (1994), I decompose $U_{ij}$ into two terms: $\delta_j$, the mean utility term common to all consumers, and $\varepsilon_{ij}$, the utility term specific to each consumer.

The consumer-specific error term $\varepsilon_{ij}$ is an individual realization of the random variable $\varepsilon$. The distribution of $\varepsilon$ determines the shape of demand and the implied substitution patterns. McFadden (1978) has proposed a family of random utility models, the Generalized Extreme Value (GEV) family, in which those patterns can be modeled in different ways according to the specific behavioral circumstances. A GEV model is derived from a generating function $G = G(e^{\delta_0, \ldots, \delta_j})$, a differentiable function defined on $\mathbb{R}_J^+$: (i) which is nonnegative; (ii) which is homogeneous of degree 1; (iii) which tends toward $+\infty$ when any of its arguments tend toward $+\infty$; (iv) whose $n$th cross-partial derivatives with respect to $n$ distinct $e^{\delta_j}$ are non-negative for odd $n$ and nonpositive for even $n$.

According to the GEV postulate, the choice probability of buying product $j$ is

$$s_j = \frac{e^{\delta_j} \cdot G_j(e^{\delta_0, \ldots, \delta_j})}{G(e^{\delta_0, \ldots, \delta_j})},$$

where $G_j$ is the partial derivative of $G$ with respect to $e^{\delta_j}$.

3There is a long tradition of estimating demand in product space assuming weak separability across product groups when defining consumer preferences, which reduces the dimensionality of the problem but imposes mutually exclusive product groupings. Blundell and Robin (2000) break weak separability by developing the concept of latent separability, in which products from different groups can interact through subutilities stemming from latent activities. While firmly in the discrete choice literature in characteristics space, my work echoes Blundell and Robin (2000) in its attempt of breaking the rigidity of nesting structure.
The ordered nested logit model  Assume that the set of products $j$ is partitioned into $N$ mutually exclusive and collectively exhaustive nests. In addition, assume that those $N$ nests are naturally ordered, with $n$ increasing along its natural ordering: $n = 1, \ldots, N$. The ordering may correspond to an increasing value of important characteristics such as price and quality. I define the Ordered Nested Generalized Extreme Value model (in short, Ordered Nested Logit) as the model resulting from the following $G$ function within the GEV class:

$$
G = \sum_{r=1}^{N+M} \left( \sum_{n \in B_r} \delta_n \left( \sum_{j \in S_n} \exp \left( \frac{\delta_j}{1 - \sigma_n} \right) \right)^{\frac{1-\sigma_n}{\sigma_n}} \right)^{1-\rho_r},
$$

where $n$ is the nest to which the products belongs; $M$ is a positive integer; $\delta_n \geq 0$ and $\sum_m \delta_m > 0$. The weight $\delta_n$ is the allocation weight of a nest into a “neighborhood of nest,” the set of nests $B$. The parameters $\sigma_n$ and $\rho_r$ are constants satisfying $0 \leq \rho_r \leq \sigma_n < 1$. Those conditions are sufficient to satisfy the four properties of GEV generating functions; Appendix A provides the proof for each condition. Finally, define the set of $N$ nests as $B_r = \{S_n \in \{S_1, \ldots, S_N\} | r - M \leq n \leq r\}$. Each of the $(N + M)$ sets contains up to $M + 1$ contiguous nests (and all the alternatives in those nests).

Consider a simple example with five nests $S$, ten alternatives and $M = 2$:

$$
\begin{align*}
  j &= 1; 3; 2; 5; 4; 6; 7; 9; 8; 10 \\
  S &= \{S_1, S_2, S_3, S_4, S_5\}
\end{align*}
$$

Alternatives within a nest need not to be ordered, but nests are. In our example, the sets of nests are: $B_1 = \{S_1\}$, $B_2 = \{S_1, S_2\}$, $B_3 = \{S_1, S_2, S_3\}$, $B_4 = \{S_2, S_3, S_4\}$, $B_5 = \{S_3, S_4, S_5\}$, $B_6 = \{S_4, S_5\}$, $B_7 = \{S_5\}$. where each nest $S_n$ belongs to $M + 1$ different sets. The degree of proximity between neighboring nests can be modeled flexibly as each set of nests can have its own parameter $\rho_r$. The shape of the demand function crucially depends on the two parameters, $\sigma_n$ and $\rho_r$, that parameterize the cumulative distribution of the error term $\epsilon$. The first one, $\sigma_n$, corresponds to a pattern of dependence in $\epsilon$ across products sharing the same nest (as in the Nested Logit). The second one, $\rho_r$, corresponds to a pattern of dependence in $\epsilon$ across products belonging to neighboring nests. Consider, for example, the effect of a price shock to alternative one belonging to segment $S_1$. The dependence in $\epsilon$ measured by $\sigma_n$ determines that a share of consumers, who had initially chosen alternative one in $S_1$, will switch to another alternative in segment $S_1$. The dependence in $\epsilon$ measured by $\rho_r$ determines that a share of consumers will switch

---

4 Small (1987), Vovsha (1997), and Bresnahan, Stern, and Trajtenberg (1997) impose the condition that the sum of the weights is equal to one. Those weights are then interpreted as allocation parameters of nests to sets of nests. As long as weights are nonnegative and at least one of the weights is strictly positive, the generating function $G$ belongs to the GEV family, as shown in Bierlaire (2006) and in Appendix A. The condition that the sum of the weights equals one is empirically useful to ensure that the estimation of the model is feasible: I make use of it in the empirical application. Using simulated data, I expand on the role of the weights and show that possible misspecifications in weights do not seem to affect the parameter estimates of interest and the resulting substitution patterns (see Section 2.3).

5 Although $B_r$ was defined as a nest of nest indices, I will sometimes write, with a slight abuse of notation, $S_n \in B_r$. 

---

1278  Laura Grigolon  Quantitative Economics 12 (2021)
to the neighboring segments: In our example, with \( M = 2 \), the neighboring segments are \( S_2 \) and \( S_3 \).

If the random components follow the \( G \) function in equation (2), by the GEV postulate in equation (1) the choice probability of buying product \( j \in S_n \) is

\[
    s_j = \sum_{r=n}^{n+M} s(j|n) \cdot s(n|B_r) \cdot s(B_r),
\]

where

\[
    s(j|n) = \frac{\exp\left(\frac{\delta_j}{1 - \sigma_n}\right)}{Z_n},
\]

\[
    s(n|B_r) = \frac{\exp(\frac{(1 - \rho_r)I_r}{1 - \rho_r})}{\exp(I_r)},
\]

\[
    s(B_r) = \frac{\exp((1 - \rho_s)I_s)}{\sum_{s=1}^{N+M} \exp((1 - \rho_s)I_s)},
\]

\[
    Z_n = \sum_{j \in S_n} \exp\left(\frac{\delta_j}{1 - \sigma_n}\right),
\]

\[
    I_r = \ln \sum_{n \in B_r} w_{r-n} Z_n \frac{1 - \sigma_n}{1 - \rho_r}.
\]

Equation (3) involves algebraic rearrangements from the choice probabilities expressed according to the GEV postulate in equation (1): Appendix A provides a derivation of this expression.

**The nested logit model** To clarify the logic of the modeling strategy for the Ordered Nested Logit, consider the \( G \) function associated with a traditional specification, the Nested Logit model, in which the ordering of the segments is not explicitly modeled. The model incorporates potential correlation among products only within a nest (segment), not between nests. The \( J \) alternatives are grouped into \( N \) nests labeled \( S_0, \ldots, S_N \). The \( G \) function takes the form:

\[
    G = \sum_{n=1}^{N} \left( \sum_{j \in S_n} e^{\frac{\delta_j}{1 - \sigma_n}} \right)^{1 - \sigma_n},
\]

where \( \sigma_n \) captures correlation among products within the same nest. Consistency with random utility maximization requires \( \sigma_n \) to lie in the unit interval. In the Nested Logit model, only alternatives belonging to the same nest have stochastic terms that are correlated, and such correlation is directly related to \( \sigma_n \). The generating function \( G \) of the Ordered Nested model in equation (2) reduces to the Nested Logit model in equation
(4) if $\rho_r = 0$. In addition, if $\sigma_n = 0$ for all nests, the model becomes the standard Logit in which each element of $\varepsilon$ is independent.

Following Berry (1994), I can write the choice probability of a product $j$ for the Nested Logit model as follows:

$$s_j = s(j|n) \cdot s(n),$$

where

$$s(j|n) = \frac{\exp\left(\frac{\delta_j}{1 - \sigma_n}\right)}{Z_n},$$

$$s(n) = \frac{Z_n^{1 - \sigma_n}}{\exp(I_n)},$$

$$Z_n = \sum_{j \in S_n} \exp\left(\frac{\delta_j}{1 - \sigma_n}\right),$$

$$I_n = \ln \sum_{n=1}^{N} Z_n^{1 - \sigma_n}.$$

Compare the market shares of the Ordered Nested Logit model in equation (3) with the market shares of the one-level Nested Logit model in equation (5): similarly to the one-level Nested Logit model, in the Ordered Nested Logit model, a change in the attributes of alternative $j$ (say, a price increase) will determine that $s_j$ is diminished by the presence of attractive alternatives within a nest $n$. Differently from the Nested Logit model, in the Ordered Nested Logit $s_j$ is also diminished by the presence of attractive alternatives in neighboring nests $B_r$. Ceteris paribus, this effect is increasing in $\rho_r$: one may expect that if the values of $\sigma_n$ and $\rho_r$ are sufficiently high, products belonging to the same segment or to neighboring segments will be closer substitutes compared to products belonging to further segments. The substitution patterns will be more precisely illustrated in the next paragraph.

### 2.1 Substitution patterns

The flexibility introduced by the Ordered Nested Logit model is easily assessed by looking at the matrix of own- and cross-price elasticities, as presented in Corollary 1, page 38 in Davis and Schiraldi (2014):

$$\frac{\partial \ln s_i}{\partial \ln p_j} = \left(I(j = i) + \frac{e^\delta_i G_{ij}}{G_i} - s_j\right)(-\alpha p_j).$$

Table 1 compares the substitution patterns implied by the Nested Logit and the Ordered Nested Logit model. The elasticities of the Ordered Nested Logit reduce to the ones of the Nested Logit if $\rho_r = 0$. More generally, the elasticities of the Ordered Nested Logit model depend not only on the conditional probability of choosing alternative $i$ in nest $n$, but also on the conditional probability of choosing nest $n$ in a set of nests $B_r$. In
Table 1: Segment elasticities: Ordered Nested Logit vs. Nested Logit.

Note: The table compares the substitution patterns generated in the Nested Logit and the Ordered Nested Logit generated according to the GEV generating functions \( G \) (first row).

Appendix A, I provide a derivation of the expressions for the first and second derivatives \( (G_i \text{ and } G_{ij}) \).

I focus on the cross-price elasticities. In the Nested Logit, when two products belong to different nests, we see that a price reduction reduces the probabilities for all the other alternatives by the same percentage, a pattern of substitution that is a manifestation of the Independence from Irrelevant Alternatives (IIA) property (cases b and c in Table 1). In the Ordered Nested Logit, if two products belong to different nests but to the same set of nests \( B_n \) (case b in the table), proportionate shifting does not hold. Another way to look at this is to focus on the ratio of probabilities between alternatives. In the Nested Logit model the second cross-partial derivative, \( G_{ij} \), is equal to zero for product \( i \) in a different nest than product \( j \). In the Ordered Nested Logit, \( G_{ij} \neq 0 \) for \( j \) in a different nest than \( j \) but in the same set of nests \( B_n \). In both the Nested Logit and the Ordered Nested Logit models, the IIA property holds for two products in the same nest, so the ratio of probabilities of alternative \( i \) and \( j \) is independent of the attributes or existence of the other alternatives. The Nested Logit model relaxes the IIA property across nests only to a certain extent: the ratio of probabilities of products in different nests will only depend on the attributes of products in nests that contain \( i \) and \( j \), but not on all other nests: Train (2009) described this property as “independence from irrelevant nests.” In contrast, in the Ordered Nested Logit this form of IIA is weakened as the ratio of probabilities of two products will depend not only on the attributes and existence of the alternatives in the two nests, but also all the alternatives in the neighboring nests.

Note that in the Random Coefficients Logit model the IIA property remains present at individual level, as the individual-level choice probabilities are a multinomial logit.
2.2 The Ordered Nested Logit versus other GEV models

The OGEV model

The OGEV model derived by Small (1987) is based on the following $G$ function (see Definition 1 in Small (1987)):

$$G = \sum_{r=1}^{J+M} \left( \sum_{j \in B_r} w_{r-j} \exp\left(\delta_j \frac{1}{1-\rho_r}\right) \right)^{1-\rho_r},$$

where $M$ is a positive integer; the weights $w_m$ are overlapping parameters for alternatives; the parameter $\rho_r$ is a measure of correlation between alternatives, rather than nests as in our model, and $B_r$ is a set of alternatives, not nests.

The OGEV model responds to different modeling needs with respect to the Ordered Nested Logit: The OGEV is designed for situations where individual-level data are available, with a limited number of alternatives can be naturally ordered. Instead, the Ordered Nested Logit model is designed for situations in which numerous alternatives are present. Groups of those alternative can be naturally ordered, while alternatives in each group do not need to be ordered.7

The Generalized Nested Logit model

The Ordered Nested Logit model can be viewed as a special case of the Generalized Nested Logit (GNL) by Wen and Koppelman (2001). Recall the generating function of the GNL model:

$$G = \sum_{k=1}^{K} \left( \sum_{j \in S_k} \alpha_{jk} \exp(\delta_j) \right)^{1-\rho_k},$$

where $S_k$ is the set of all alternatives included in nest $k$, $\alpha_{jk}$ is the allocation parameter which is the portion of alternative $j$ assigned to nest $k$.

The Ordered Nested Logit model can be written as a special case of the GNL if (i) alternatives are positioned in the nest to which they originally belong, so $S_n = \{j \in S_n\}$; (ii) all the alternatives in neighboring nests are put together in a nest $B_r$ formed by combinations of nests in ordered position: $B_r = \{S_n \in \{1, \ldots, N\} | r - M \leq n \leq r\}$; (iii) the weights or allocation parameters $\alpha_{jk}$ are equal for all alternatives in nest $B_r$. Hence, weights are associated to the nest $B_r$ rather than its alternatives.

Summary

The Ordered Nested Logit model generalizes the Nested Logit model by capturing asymmetric interactions across nests. It differs from the OGEV model by Small (1987) because it is designed to capture asymmetric interactions across nests, not across alternatives. Hence, it does not impose an order across alternatives, but across groups of alternatives (nests). The Generalized Nested Logit model by Wen and Koppelman (2001) is the most general instance of a GEV model, but the complexity requires normalization.

---

7The Ordered Nested Logit model also differs with respect to the nested version of the OGEV model described by Small (1994) and Bhat (1998), which is similar to a nested logit except that at the lower node the alternatives (not segments) are grouped according to the OGEV model rather than the standard logit.
assumptions to identify the parameters and constraints to make the estimation feasible: see Bierlaire (2006). The Ordered Nested Logit includes an ordered nesting structure motivated by features commonly found in differentiated product markets: Those restrictions render the model easy to handle for estimation while retaining flexibility.

2.3 Simulated data

The Ordered Nested Logit model is appealing for its closed-form formulation and its ability to capture more complicated substitution patterns than the Nested Logit. As a first step to test the benefits of the Ordered Nested Logit model, I consider two main sets of Monte Carlo experiments. In the first experiment, I generate data according to the Ordered Nested Logit model and fit the Nested Logit. In the second experiment, I generate data according to a Random Coefficients Logit and fit the Ordered Nested Logit model. All the details on the experiments and the tables are reported in the Online Supplementary Material in Appendix B (Grigolon (2021)).

The experiments have three objectives: (i) to assess the flexibility of the Ordered Nested Logit in approximating the correct substitution patterns under various models; (ii) to evaluate the consequences of product misallocation to nests; (iii) to provide guidance on the design of the nesting structure, in particular on the number of nests ($N$), neighboring nests ($M$), and the role of weights. A summary of the results follows.

(i) Substitution patterns When comparing the segment-level elasticities between the correctly specified Ordered Nested Logit and the Nested Logit model in Table B.2, we clearly see that the Nested Logit model delivers symmetric substitution patterns outside a segment: asymmetries are ruled out by construction. When comparing the substitution patterns delivered by the correctly specified Random Coefficients Logit versus the misspecified Ordered Logit in Table B.5, the Ordered Nested Logit approximates well the asymmetric substitution pattern generated by the Random Coefficients Logit model even if the model is misspecified, with a slight overestimation of substitution toward the most immediate neighbor and underestimation toward the distant ones.

(ii) Product misallocation Both the Nested Logit and the Ordered Nested Logit models require partitioning the products into nests: in Table B.3, I show that the Ordered Nested Logit model is less sensitive to misclassification of products into nests with respect to the Nested Logit. The bias in the own- and cross-price elasticities resulting from a misspecified Ordered Nested Logit is always smaller than the one resulting from a misspecified Nested Logit model.

(iii) Design of the nesting structure I provide guidance on the nesting structure, with a focus on (i) the choice of the number of nests ($N$); (ii) the choice of the number of neighboring nests ($M$); (iii) the nesting weights. The results can be summarized as follows:

---

8As the Ordered Nested Logit is a special case of the Generalized Nested Logit or the Cross-Nested Logit model proposed by Bierlaire (2006), one can also follow the proof offered in Bierlaire (2006) to verify the properties of the generating function $G$. 
(i) If the researcher specifies nests too narrowly, both the nesting parameter $\sigma$ and the neighboring nesting parameter $\rho$ present an upward bias, so much so that the neighboring nesting parameter may be even greater than nesting parameters ($\rho > \sigma$), which is inconsistent with random utility maximization.

(ii) By introducing the parameter $M$ governing which nests are correlated, the Ordered Nested Logit model gives another dimension of choice to the researcher. If only the immediately proximate neighbor matters ($M = 1$), while the researcher allows for $M = 2$, the nesting parameter $\sigma$ presents a downward bias, and the neighboring nest parameter $\rho$ an upward bias. This may result in $\rho > \sigma$. The pattern is reversed if the correct DGP suggests more flexibility in terms of number of neighbors ($M = 2$), while the researcher uses $M = 1$: the estimated nesting parameter presents an upward bias and the neighboring nesting parameter a downward bias. In general, a researcher may want to pursue as much flexibility as possible ($M > 1$), but doing so may determine situations where the neighboring nesting parameter is greater than nesting parameters ($\rho > \sigma$), which is, again, inconsistent with random utility maximization;

(iii) Direct estimation of the weight coefficients requires the use of additional instruments and the estimates tend to be rather imprecise. I also assess the role of the weight choice by estimating a model in which fixed weights are intentionally misspecified (not estimated). I find that the demand parameters are hardly impacted by the misspecification; the substitution patterns are close to the true ones. In conclusion, possible misspecifications in weights do not seem to affect the parameter estimates of interest and the resulting substitution patterns.

3. Empirical study

3.1 Data

I now turn to the application of the Ordered Nested Logit to the automobile market. For the empirical study, I combine different data sets. The main one is a data set on the automobile market provided by a marketing research firm, JATO: it includes essentially all transactions of passenger cars sold between 1998 and 2011 in the three largest European car markets: France, Germany, and Italy. The data is highly disaggregated, and I aggregate it at the level of the car model (nameplate), for example, Volkswagen Golf. For each car model/country/year, I have information on sales, prices, and various characteristics such as vehicle size (curb weight, width, and height), engine attributes (horsepower and displacement), fuel consumption (liter/100 km or €/100 km), emissions, the brands’ specific perceived country of origin, and for models introduced or eliminated within a given year, the number of months with positive sales. I define a model as a combination of brand/model/body type. An “engine variant” is a combination of fuel engine type (gasoline or diesel), displacement, and horsepower; see Grigolon, Reynaert, and Verboven (2018) for details. For example, a “Volkswagen Golf hatchback” is a model, whereas the engine variant is: “gasoline, 1390cc, 59 kW”. The base model is: (i) the gasoline engine type, unless the car is sold only in the
prices, and GDP. Low-sold car models, which are more susceptible to recording or measurement errors, as well as non-passenger cars, such as pickups and large vans, are removed. I also exclude minivans, sports cars, and sport utility vehicles because they do not naturally fit in a univocal ordering of the segments, for example, sports cars are on average more powerful but not more expensive than luxury cars. The resulting data set consists of 5788 model/country/year observations or, on average, about 138 models per country/year.\textsuperscript{10}

Prices are list prices including value added taxes and registration taxes, which differ across countries and engines: such information comes from the European Automobile Manufacturers Association. Prices are also corrected to account for active scrapping schemes and feebate programs according to the eligibility criteria for each vehicle: information on those programs comes from IHS Global Insight (an automotive consultant) and the European Automobile Manufacturers Association. Finally, the data set is augmented with information on the location of the main production plant for each car model (from PWC Autofacts), and three input prices by country of production: unit labor costs, steel prices, and a producer price index. Table 2 presents summary statistics for sales, price, and vehicle characteristics used in demand estimation.

Starting from JATO’s classification, I attribute each model to a marketing segment. I define five segments: subcompact, compact, standard, intermediate, and luxury.\textsuperscript{11} Cars belonging to the same segment share similar characteristics in terms of price, horsepower, fuel consumption, and size. Segmentation is used by car makers to position their vehicle in the market place; they often advertise their vehicle as the cheapest or best

\begin{table}[h]
\centering
\begin{tabular}{lcc}
\hline
 & Mean & Std. Dev. \\
\hline
Sales (units) & 13,821 & 24,312 \\
Price/Income & 0.84 & 0.50 \\
Power (in kW) & 82.19 & 35.72 \\
Fuel efficiency (€/100 km) & 7.27 & 1.46 \\
Size (m\textsuperscript{2}) & 7.46 & 1.14 \\
Foreign (0–1) & 0.78 & 0.42 \\
Months present (1–12) & 9.66 & 2.61 \\
\hline
\end{tabular}
\caption{Summary statistics.}
\end{table}

\textit{Note:} The table reports means and standard deviations of the main variables. The total number of observations (models/markets) is 5788, where markets refer to the 3 countries and 14 years.

\textsuperscript{10}The model could be extended to incorporate multidimensionality in ordering. One could parametrize the potential correlation among products along two (or more) dimensions of ordering by taking the weighted sum of two Ordered Nested Logit generating function $G(\cdot)$ as follows:

$$G(e^\delta) = \alpha_{d1} G_{d1} + \alpha_{d2} G_{d2},$$

where $d1$ and $d2$ denote dimension 1 and dimension 2 of the ordering.

\textsuperscript{11}For example, a Volkswagen Golf belongs to the compact segment. The smaller Polo belongs one segment below the Golf (subcompact), while the bigger Passat is located one segment above (intermediate).

*Note:* The top panel of the table reports means of the main variables per segment in the top panel. The bottom panel of the table reports the percentage of correctly classified car models, based on binary logit of a segment dummy per pair on four continuous characteristics (i.e., power, fuel efficiency, width, and height). Subcomp. = subcompact, Interm. = intermediate.

Performing in its class. Leading automotive magazines, such as *Auto Motor und Sport*, award a “best car” prize for each segment. Comparison web sites and consumer reports also feature the classification into segments as a prominent search tool. But the boundaries between segments are blurred by the presence of cars with some characteristics, including price, image, and extra accessories, which would position those cars in an upper segment. Audi A1 or BMW Mini are examples of “luxury subcompacts” designed to compete across segments. Table 3 and Figure 1 provide a descriptive illustration of segmentation in the car market. The top panel of the table presents the mean and standard deviation of price, horsepower, fuel consumption, and size by segment. Figure 1 represents also the median, the minimum, and maximum values, and the values of the lower and upper quartiles of those characteristics. The table and the figure illustrate that the mean and median values of all characteristics increase from subcompact to luxury (with the exception of size from the intermediate to standard segment). At the same time, the large variability displayed by those characteristics within a segment suggest that some overlap across segments is plausible and depends on the proximity of the ordering. The bottom panel of Table 3 shows how well characteristics predict to which segment each car model belongs. Classifications are reasonably accurate (always above 80% with one exception), but the prediction power is not perfect and confirms the need to quantify the presence of neighboring segment effects.

#### 3.2 Specification

To estimate the demand for cars in France, Germany, and Italy, I modify the Ordered Nested Logit specified above. In each period (year) and country $t$, $L_t$ potential con-
consumers choose one alternative, either the outside good \( j = 0 \) or one of the \( J \) cars. Following Berry (1994) and the subsequent literature, price is treated separately because it is an endogenous characteristic. The outside good includes the option “do not buy a product,” \( j = 0 \) for which consumer \( i \)'s indirect utility is \( u_{i0} = \varepsilon_{i0} \). For cars \( j = 1, \ldots, J \), the utility specification is

\[
U_{ijt} = x_{jt} \beta - \alpha_i p_{jt} + \xi_{jt} + \epsilon_{ijt} = \delta_{jt} - \alpha_i p_{jt} + \epsilon_{ijt},
\]

where \( x_{jt} \) is a \( 1 \times K \) vector of characteristics including price, horsepower, fuel consumption, size measures (width and height), and a dummy variable for the country of origin. For the potential market size \( L_t \), I follow the literature and use the total number of households in each year and market.

In estimation, the coefficient of price, \( \alpha_i \), is specified in two ways: (i) \( \alpha_i = \alpha / y \), where \( y \) is equal to income per capita; (ii) \( \alpha_i = \alpha / y_i \), a specification in which I exploit information on income distribution. Both specifications imply that households with higher income are less sensitive to price.\(^{12}\)

\(^{12}\)Specifically, I take advantage of the easily available information on the percentage of the total income attributable to each decile of population. I couple this information with aggregate income by country (\( y \))
The error term \( \varepsilon_{ij} \) is the individual realization of the random variable \( \varepsilon \): as discussed above, its distribution determines the substitution patterns. I assume that the \( 5 + 1 \) nests (segments) are ordered as follows: \( S_0 \), the outside good; \( S_1 \), subcompact; \( S_2 \), compact; \( S_3 \), standard; \( S_4 \), intermediate; and \( S_5 \), luxury. The ordering corresponds to an increasing value of observable and unobservable characteristics such as price, size, comfort, and performance. The outside good nest is the nest with the “inferior quality” good.\(^{13}\)

The distribution of the error term \( \varepsilon_{ij} \) thus follows the assumptions of the Ordered Nested Logit as defined in equation (2). To obtain as much flexibility as possible, I assume that \( M = 2 \), so that each segment \( S \) has two contiguous segments as neighbors, or, in other words, each segment belongs to 3 different sets of segments \( B \). In sum, I have \( 6 + 2 \) sets containing up to 3 contiguous nests (and all the alternatives in those nest):

\[
B_0 = \{S_0\}, \\
B_1 = \{S_0, S_1\}, \\
B_2 = \{S_0, S_1, S_2\}, \\
B_3 = \{S_1, S_2, S_3\}, \\
B_4 = \{S_2, S_3, S_4\}, \\
B_5 = \{S_3, S_4, S_5\}, \\
B_6 = \{S_4, S_5\}, \\
B_7 = \{S_5\}.
\]

The nesting parameter \( \sigma_n \) differs across the 5 nests. While the model theoretically has 8 neighboring nest parameters \( \rho_r \) (one for each set of nests \( B_r = 0, \ldots, 7 \)), I impose the following structure to avoid the proliferation of parameters and issues in identification. As the decision to choose the outside option is fundamentally different from the decision to choose one of the alternatives in the choice set, I estimate one neighboring nest parameter for the sets containing the outside option \( (B_0, B_1, B_2) \), and one neighboring nest parameter for the sets containing the inside good \( (B_3, B_4, B_5, B_6, B_7) \). This implies the estimation of 7 random coefficients: 5 nesting parameters \( \sigma \) and 2 parameters determining the degree of proximity between groups of nests, \( \rho_0 = \rho_1 = \rho_2 \) and \( \rho_3 = \rho_4 = \rho_5 = \rho_6 = \rho_7 \). Finally, for simplicity all nests are assigned the same weight \( 1/(M + 1) = 1/3 \).

\(^{13}\)The industry and the European Commission have at times used more detailed classifications, for example, by distinguishing the subcompact segment between city/mini cars and small cars (segment A and B). When using more detailed classifications, I found that the model was not supported in the data \( (\rho_r > \sigma_n) \). The result is consistent with the Monte Carlo analysis when nests are narrowly defined.
3.3 The estimation procedure

The estimation procedure for the Ordered Nested Logit model follows the methodological lines of Berry (1994), Berry, Levinsohn, and Pakes (1995), and the subsequent literature. I exploit the panel features of the data set to specify the product-related error term as follows: $\xi_{jt} = \xi_j + \xi_t + \Delta \xi_{jt}$, where $\xi_j$ is a fixed-effect for each car model, $\xi_t$ is a full set of country/year fixed effects, and a set of dummy variables for the number of months each model was available in a country within a given year (for models introduced or dropped within a year). $\Delta \xi_{jt}$ is the remaining product-related error term.

The estimation procedure is standard in the literature. First, I numerically solve for the error term $\Delta \xi_{jt}$ as a function of the vector of parameters. Second, I interact $\Delta \xi_{jt}$ with a set of instruments to form a generalized method of moments (GMM) estimator. Consider the solution of $\Delta \xi_{jt}$ first. In the Nested Logit model, $\Delta \xi_{jt}$ has an analytic solution. In the Ordered Nested Logit model, $\Delta \xi_{jt}$ is the numerical solution of the system $s = s(\delta, \alpha, \sigma_n, \rho_r)$. I use a modified version of Berry, Levinsohn, and Pakes’s (1995) contraction mapping: $\delta^{k+1} = \delta^k + [1 - \max(\hat{\sigma}_n, \hat{\rho}_r)] \cdot [\ln(s_t) - \ln(s_t(\delta^k))]$. If one does not weigh the second term by $[1 - \max(\hat{\sigma}_s, \hat{\rho}_r)]$, the procedure may not lead to convergence; see Appendix A in Grigolon and Verboven (2014).

Let $\hat{\Delta} \xi$ be the sample analogue of the vector $\Delta \xi$, and $Z$ the matrix of instruments. The GMM estimator is defined as

$$\min_{\alpha, \sigma_n, \rho_r} \hat{\Delta} \xi'(Z \Omega Z') \hat{\Delta} \xi,$$

where $\Omega$ is the weighting matrix. I follow a two-step procedure: First, I use the weighting matrix $\hat{\Omega} = (Z'Z)^{-1}$. Then I reestimate the model with the optimal weighting matrix. To minimize the GMM objective function with respect to the parameters $\alpha$, $\sigma_n$, $\rho_r$, I first concentrate out the linear parameters $\beta$. Also, I do not directly estimate more than 200 car model fixed effects $\xi_j$, but instead use a within transformation of the data (Baltagi (1995)). Standard errors are computed using the standard GMM formulas for asymptotic standard errors. Following Dubé, Fox, and Su (2012), I use a tight tolerance level to invert the shares using the contraction mapping $(1e - 12)$, check convergence for 10 starting values at each step, and check that the first-order conditions are satisfied at convergence.

3.4 Identification

The GMM estimator requires an instrumental variable vector $Z$ with a rank of at least $K + 8$ ($K$ is the dimension of the $\beta$ vector; the price parameter $\omega$; the five nesting parameters $\sigma_n$ and the two parameters characterizing correlation between neighboring nests $\rho_r$). The interpretation of $\Delta \xi_{jt}$ as unobserved product quality disqualifies price $p_{jt}$ as an instrument since it could imply a positive correlation with $\Delta \xi_{jt}$. There are two main reasons for such correlation. First, if an unobservable characteristic, for example, comfort, rises with price, consumers will avoid expensive cars less than they would without that characteristic. Second, if adding comfort is costly for the manufacturer, the price of the car is expected to reflect this cost. A similar argument holds for the correlation...
between the shares within a segment or within neighboring segments and \( \Delta \xi_{jt} \): parameters \( \sigma_n \) and \( \rho_r \) are special kinds of random coefficients (Cardell (1997)). Berry and Haile (2014) clarify that, even abstracting from price endogeneity, identification of random coefficients requires instrumentation for the endogenous market shares; this calls for instrumentation of the share terms.

Following Berry, Levinsohn, and Pakes (1995), I assume that the observed product characteristics \( x_{jt} \) are uncorrelated with the unobserved product characteristics \( \Delta \xi_{jt} \), so product characteristics \( x_{jt} \) are included in the matrix of instruments. Note that this assumption is weaker than the often adopted assumption that \( x_{jt} \) is uncorrelated with \( \xi_{jt} \).

I include three sets of moment conditions. The first set focuses on the identification of the price coefficient. Armstrong (2016) suggested the use of cost-shifters, especially when the number of products is large, to identify price effects. I use input prices derived from the country of production of each car: a steel price index interacted with car weight (as a proxy for material costs), unit labor costs in the country of production, and a dummy for whether the country of production and destination are the same.\(^{14}\)

The second set of instruments, often used in the literature, includes interactions of the exogenous characteristics. In particular, I use (i) counts and sum of the characteristics of other products of competing firms by segment; (ii) counts and sum of the characteristics of other products of the same firm by segment; (iii) counts and sum of the characteristics of other products of competing firms by a set of segments \( B_r \); (iv) counts and sum of the characteristics of other products of the same firm by a set of segments \( B_r \). These instruments originate from supply side considerations, where I assume that firms set prices according to a Bertrand–Nash game. When the number of products in one segment, or in the neighboring segments increases, demand should become more elastic and this should affect prices and shares. Similarly, if one firm produces a large share of the products in one segment or in neighboring segments, sales and prices for each product of that particular firm should be higher.

Following Gandhi and Houde (2019), the third set of instruments is the difference in car attributes to capture the relative position of each product in the characteristic space. Those instruments approximate the optimal instrumental variables I used with simulated data without requiring initial estimates.\(^{15}\) In particular, I construct the sum of square of characteristic differences within each segment and within each set of segments, \( B_r \).\(^{16}\)

\(^{14}\)In the data, car models are produced in 23 different countries. As a test for weak instruments, I run a simple logit model using these three instruments for price, while accounting for heteroskedastic errors. The F-test is 35.1, above 10, the rule-of-thumb proposed by Staiger and Stock (1997). The effective F-statistic (Olea and Pflueger (2013)) equals 31.6, which is above 18.97 for 5% maximal bias relative to OLS.

\(^{15}\)With simulated data, I did not need to use any approximation because I constructed the optimal instruments from the parameters and the functional form assumptions of the true data generating process.

\(^{16}\)A flexible Random Coefficients Logit would also obtain realistic substitution patterns. In the Online Supplementary Material in Appendix B, Specification 2, I use a Random Coefficients Logit specification with a flexible matrix of parameters governing the heterogeneity in preferences, which allows consumer valuations to be correlated across characteristics. Gandhi and Houde (2019) provide an insightful discussion on the identification of correlated random coefficients. They use interactions between continu-
4. Results

4.1 Demand estimates

Table 4 shows the parameter estimates for four specifications. The first one (Nested Logit I) is the one-level Nested Logit model, which imposes $\rho_r = 0$. The second specification (Order Nested Logit I) is an Ordered Nested Logit with $M = 2$; both $\sigma_s$ and $\rho_r$ are estimated and the coefficient of price, $\alpha_i$, is specified as $\alpha/y$, where $y$ is equal to income per capita of each country. The third specification (Nested Logit II) is a Random Coefficients Nested Logit, which again imposes $\rho_r = 0$ but allows for heterogeneity in price sensitivities, so that $\alpha_i = \alpha/y_i$. Finally, the fourth specification (Order Nested Logit II) is an Ordered Nested Logit identical to the second specification, in which we have both $\sigma_s$ and $\rho_r$, with the addition of heterogeneity in price sensitivities: $\alpha_i = \alpha/y_i$.

Note: The table shows the parameter estimates and standard errors for the three demand models: (i) the Nested Logit model, which assumes homogenous income distribution ($\alpha_i = a/y$) and set the neighboring segmentation parameter at zero ($\rho = 0$); (ii) the Ordered Nested Logit I with homogenous income distribution ($\alpha_i = a/y$) and two neighboring nest parameters, one for the sets containing the outside option ($B_0$, $B_1$, $B_2$), and one for the sets containing the inside good ($B_3$, $B_4$, $B_5$, $B_6$, $B_7$); (iii) the Nested Logit with heterogeneous income distribution ($\alpha_i = a/y_i$) and two neighboring nest parameters, one for the sets containing the outside option ($B_0$, $B_1$, $B_2$), and one for the sets containing the inside good ($B_3$, $B_4$, $B_5$, $B_6$, $B_7$); (iv) the Ordered Nested Logit with heterogeneous income distribution ($\alpha_i = a/y_i$) and two neighboring nest parameters, one for the sets containing the outside option ($B_0$, $B_1$, $B_2$), and one for the sets containing the inside good ($B_3$, $B_4$, $B_5$, $B_6$, $B_7$). The total number of observations (models/markets) is 5788, where markets refer to the 3 countries and 14 years. NL = Nested Logit.
Allowing heterogeneity in price sensitivity is useful for two reasons. First, if a researcher believes that coefficients on both market segmentation and some continuously measured characteristics are random, a “mixed” Ordered Nested Logit model can represent well such situation. Including a random coefficient on price is useful to illustrate the flexibility of the model. Second, modeling heterogeneity in price sensitivities is important because of the focus on price elasticities, especially when considering demand for large budget share products, such as cars. The Ordered Nested Logit model is well suited to capture heterogeneity attributable to market segmentation, and does so more flexibly than the Nested Logit while retaining tractability. At the same time, price sensitivity is a particularly relevant aspect of heterogeneity that may not be completely captured by market segmentation alone. Adding a random coefficient to the Ordered Nested Logit is a tractable solution to flexibly account for heterogeneity in both dimensions. As the random coefficient on price is based on the income distribution, it also accounts for differences in prices and market shares attributable to differences in the distribution of income across countries. Of course, this comes at the cost of losing the closed-form solution for market shares, but can be reasonable to capture the features of the market under study.

In all four models, the price parameter ($\alpha_i$) and the parameters of the characteristics ($\beta$) have the expected sign and are all significantly different from zero. Most parameter estimates have also roughly the same magnitude. In the Nested Logit model I (Column 1), the nesting parameters are all precisely estimated; their magnitude is consistent with random utility maximization ($0 \leq \sigma_n < 1$) and (nonmonotonically) decreases from subcompact to luxury: Consumer preferences are more homogeneous for subcompact cars ($\sigma_1 = 0.95$) with respect to luxury cars ($\sigma_5 = 0.35$). This is consistent with earlier findings by Goldberg and Verboven (2001) and Brenkens and Verboven (2006). Higher values of $\sigma_n$ also imply stronger within group substitution relative to substitution to the outside option.

In the second specification, the Ordered Nested Logit I (Column 2), parameters $\sigma_n$ are again precisely estimated and nonmonotonically decreasing. The first neighboring nesting parameter, capturing correlation between proximate nests when the outside nest option is included, is low in magnitude and imprecisely estimated ($\rho = 0.13$); the second neighboring nesting parameter is precisely estimated and indicates that correlation between neighboring segments is strongly supported by the data: $\rho = 0.68$ with a standard error of 0.08. The null hypothesis of $\rho = 0$ assumed by the Nested Logit is rejected against the alternative hypothesis of a more general Ordered Nested Logit model; in other words, the Nested Logit I is rejected against the more general Ordered Nested Logit I.

The third and fourth specifications are identical to the first and the second, with the addition of heterogeneity in price sensitivity. Again, the estimates of $\sigma_n$ are significantly different from zero in both models. For the Ordered Nested Logit II, the null hypothesis of $\rho = 0$ assumed by the Nested Logit II is again rejected. In sum, both heterogeneity in price and in market segmentation are important as demonstrated by the Ordered...
Nested Logit II: when adding the dimension of price heterogeneity, correlation between neighboring segments remains relevant.\footnote{17}

The Ordered Nested Logit I and the Nested Logit II are nonnested models. I use the test proposed by Rivers and Vuong (2002) for selection among misspecified nonnested models, where the selection criteria is based on the value of the GMM objective function. In particular, I use values of the first-step objective function, employing the same estimator of the weighting matrix, based on the same set of instruments. The test statistic is \( T = \frac{(Q_1 - Q_2)}{\hat{\sigma}} \), where \( Q_i \) is the value of the GMM function of model \( i \), and \( \hat{\sigma} \) the estimated value of the standard deviation of the difference between \( Q_i \)'s.\footnote{18} The test shows that the Ordered Nested Logit I is asymptotically “better” (less misspecified) with respect to the Nested Logit II. I interpret the result as evidence that correlation between neighboring segments matters more in this data with respect to the another dimension of heterogeneity, price sensitivity.

Finally, all models imply similar own-price elasticities; demand is always elastic, which is consistent with oligopolistic profit maximization.

4.2 Substitution patterns: Segment-level price elasticities

The implications of rejecting the Nested Logit in favor of the Ordered Nested Logit model are most clearly illustrated by the implied substitution patterns at segment level. Table 5 presents own- and cross-price elasticities constructed by simulating the effect on demand of a joint 1\% price increase of all cars in a given segment.

The own-price elasticities across the four models are similar in terms of magnitude and tend to be higher for the most expensive classes. The monotonic relationship between own-price elasticity and price is the result of the assumption that price enters utility linearly and is clearly mitigated by modeling heterogeneity in consumer preferences for segments (\( \sigma_n \) and \( \rho_r \)) and especially income: see Nested Logit II and Ordered Nested Logit II.

The cross-price elasticities are the most interesting results. By construction, the one-level Nested Logit model implies a fully symmetric substitution pattern, namely identical cross-price elasticities in each row. Thus, a 1\% price increase to all subcompact cars raises demand in the compact and luxury segments by the same amount, 0.01\%. By contrast, the Ordered Nested Logit model delivers more plausible substitution patterns.

\footnote{17}I formally test (i) the Nested Logit I against the Ordered Nested Logit I, and (ii) the Nested Logit II against the Ordered Nested Logit II by using the likelihood ratio test adapted to the GMM context, where the likelihood ratio statistic is defined as the difference between the value of the objective function of the restricted model and the value of the objective function of the unrestricted model (Hayashi (2000)). Under the null hypothesis, the statistic is asymptotically \( \chi^2 \) distributed with degrees of freedom equal to the number of restrictions. Each restricted model is rejected against the more general model.

\footnote{18}The variance of the difference is estimated using bootstrap simulations, with resampling of the independent markets \( t \). The null hypothesis is that the two nonnested models are asymptotically equivalent. The first alternative hypothesis (\( H_1 \)) is that model 1 is asymptotically “better” (less misspecified) than model 2; the second alternative hypothesis (\( H_2 \)) is that model 2 is asymptotically better than model 1. The value of \( T \) is compared to the critical values of a standard normal; with \( \alpha \) denoting the size of the test and \( t_{\alpha/2} \) the value of the inverse standard normal distribution evaluated at \( 1 - \alpha/2 \). If \( T > t_{\alpha/2} \), \( H_0 \) is rejected in favor of \( H_1 \); if \( T < -t_{\alpha/2} \), \( H_0 \) is rejected in favor of \( H_2 \). Otherwise, \( H_0 \) is not rejected.
Segment is increased by 1% + two proximate segments: compact (1%) and standard (22%) compared to luxury (41%). These numbers are comparable to the ones reported by Grigolon and Verboven (2014) in the analysis of the segment-level price elasticities for the Random Coefficients Logit model. The Ordered Nested Logit model I is flexible, but still parsimonious in the number of parameters, so that only the two immediately proximate segments (on the left and on the right) are the neighboring ones. Outside the neighboring segments, the Ordered Nested Logit model still retains the modeling assumptions of the Nested Logit model. Thus, substitution patterns are symmetric outside the neighboring segments.

In the third and fourth models, the property of symmetry outside proximate segments does not hold as both models also incorporate a random coefficient on price. However, cross-price elasticities are still quite symmetric in the Nested Logit II. In the Ordered Nested Logit II, the cross-price elasticities are asymmetric, albeit such asymmetry is slightly less pronounced with respect to the Ordered Nested Logit I.
5. **Counterfactuals**

*Entry of premium subcompact* Since the early 2000s, luxury brands have entered the lower segments of the car market, such as subcompacts and compacts. The vehicles launched by those brands feature distinctive characteristics with respect to the incumbents: for their power, accessories, image, and, of course, price they resemble a vehicle from a higher segment. This trend has diluted the traditional borders between segments in the automobile market. I consider in particular three premium subcompacts: Audi A1, BMW Mini (both the hatchback and wagon versions), and the Fiat 500 Abarth, an upgraded version of the Fiat 500. Table C.11 in the Online Supplementary Material in Appendix C (Grigolon (2021)) presents summary statistics of the characteristics of those three vehicles compared to the average subcompact and compact car. Their price and horsepower are significantly higher, while there is no statistically significant difference in fuel consumption and size with respect to the average subcompact car. In contrast, with respect to the average compact car, only size is significantly lower.

I simulate a counterfactual scenario without those three premium subcompacts. Table 6 summarizes the implied diversion ratios by segment. Those ratios measure the fraction of sales diverted to other products, in the same segment or other segments, when the premium subcompacts are removed. In the simulation, I account for the response of other car makers by solving the differentiated product model for the change in equilibrium prices induced by the removal of the products. The Nested Logit model suggests that, absent the choice of premium subcompacts, 95% of sales would be diverted to other subcompact cars, while sales of upper segments would practically not be affected. The Ordered Nested Logit I, which allows for the possibility of asymmetric correlation between neighboring nests, still predicts that most substitution (93%) happens within the subcompact segment, but now 2% of sales would be diverted to compact cars. In both cases, the diversion ratio to the outside good is around 5%.

The Nested Logit II (with heterogeneity in price sensitivity) yields a slightly higher increase in sales of compact cars with respect to the Nested Logit (0.24 versus 0.10). In

Note: The table reports the diversion ratios (in percent) by segment after removing three premium subcompact car models: Audi A1, BMW Mini (both the hatchback and wagon versions) and the Fiat 500. Diversion ratios: share of fraction of sales diverted to other products in the same segment or other segments. The simulations are based on the parameter estimates in Table 4. They refer to Germany in 2011.
contrast, the Ordered Nested Logit II, which incorporates heterogeneity in price sensitivity as well, predicts that 4.7% of sales are diverted to the compact segment, and 11.6% to the outside good. Both the Nested Logit II and the Ordered Nested Logit II predict similar patterns of substitution toward the outside good.

**The effects of targeted environmental policies** Asymmetric substitution patterns across segments are particularly important when looking at asymmetric policies. An example is a targeted scrapping scheme, which encourages consumers to scrap an old vehicle and purchase a cleaner one. The data set comprises: (i) the 2009 German scrapping scheme, which was not targeted (it provided an incentive to purchase a new car regardless of its fuel efficiency); (ii) the 2008–2011 French scrapping scheme, which was targeted, and the feebate program (Bonus/Malus); (iii) various Italian scrapping schemes, which are mostly targeted but not sizeable. The French scrapping scheme in combination with the feebate program is the only notably asymmetric policy. In practice, cleaner cars in the data set mostly received only a modest rebate (€200), while polluting cars were mostly subject to a modest fee ranging from €200 to 750. Cars emitting more than 160g of CO$_2$ per kilometer would be subject to the sizeable fee of €2600, but only a handful of cars in the data meet the requirement, so the asymmetry in the policy is limited.

What would be the effect of a bolder environmental policy? I simulate the impact of a €5000 subsidy to cars emitting less than 140g of CO$_2$ per kilometer. The first column of Table 7 illustrates the asymmetry of the policy as it mostly benefits subcompact and

*Note: The table reports the effect of €5000 subsidy to cars emitting less than 140g of CO$_2$. The simulations are based on the parameter estimates in Table 4. They refer to Germany in 2011.*

19For more information, see Table A1 of Grigolon, Leheyda, and Verboven (2016) and Table 1 of D’Haultfoeuille, Givord, and Boutin (2014).

20I tested the predictions of the four models to the French environmental policy. In particular, I compare the market shares observed in 2007 (before the policy) and the simulated market shares of 2008 setting the environmental policy to zero and the fuel prices at the level of 2007. Table C.12 in the Online Supplementary Material in Appendix C shows that the four models, though suffering from the limitations of a static framework, predict counterfactual shares that are very close to the observed ones. The Ordered Nested Logit models imply counterfactual shares similar to the ones produced by the Nested Logit models because the asymmetry in the policy is actually rather limited.
compact cars. The other columns simulate the effect of the subsidy. As in the previous counterfactual, I account for the pricing responses of manufacturers. Under the Nested Logit model, subcompact cars gain a significant amount of sales (+24%). Also for the compact and intermediate segments sales increase, but by a smaller amount. Most importantly, standard and luxury cars are unaffected by the policy. The Ordered Nested Logit I model tells another story: sales of noneligible cars, especially in the standard segment, are affected by the policy and decrease by 4.2%. The Ordered Nested Logit II predicts a similar lower decrease (3%).

6. Conclusion

I present a new member of the GEV model family denominated Ordered Nested Logit model. The Ordered Nested GEV model is appealing for three reasons. First, it provides a modeling theory that is more consistent with the particular structure of choices in some segmented markets, such as cars, than a simple Nested Logit model. It creates the potential for neighboring segment effects, or, more precisely, asymmetric substitution patterns across segments. Second, the model relaxes the hierarchical nesting structure imposed by the Nested Logit model while avoiding the use of simulation as in the Random Coefficients Logit model. Third, the Ordered Nested GEV model has the Nested Logit and the Logit as special cases. It can thus serve as a test for the validity of the constraints imposed by the Nested Logit and, a fortiori, the Logit model.

I apply the Ordered Nested Logit model to the car market, which is classified into segments that are naturally ordered from subcompact to luxury. Results show that neighboring segment effects are strongly supported in the data. I show that asymmetry in substitution matters when simulating the introduction of vehicles combining features from different segments, such as premium subcompacts, or when studying the consequence of asymmetric policies, such as targeted subsidies.

The model I propose here can be a promising starting point to capture neighboring segment effects. Future research on other industries, such as retail brands, lodging, and restaurants, could benefit from this modeling strategy: Ordering a high number of alternatives can prove impossible, but ordering groups of these alternatives may represent a sensible way to obtain flexible substitution patterns in a tractable setting.

APPENDIX A

A.1 Proof GEV

PROPOSITION 1. The following conditions are sufficient for equation (2) to define a GEV generating function:

(i) $M$ is a positive integer;

(ii) $\sigma_n$ and $\rho_r$ are constants satisfying $0 \leq \rho_r \leq \sigma_n < 1$;

(iii) $w_m \geq 0$ and $\sum_m w_m > 0$. 
Proof. The four properties of GEV generating functions are verified as follows. To simplify the notation, let $e^δ = Y_j$.

1. $G$ is nonnegative since $Y_j \in \mathbb{R}_+ \forall j$, weights are nonnegative and at least one weight is strictly positive (condition (iii))

2. $G$ is homogeneous of degree 1, that is, $G(λY_0, \ldots, λY_J) = λG(Y_0, \ldots, Y_J)$,

$$G(λY_0, \ldots, λY_J) = \sum_{r=1}^{N+M} \left( \sum_{n \in B_r} \sum_{j \in S_n} \exp(\frac{1}{1-σ_n}Y_j^{-\sigma_n}) \right)^{1-σ_n} \right)^{1-ρ_r} \right)$$

3. The limit property holds since weights are nonnegative and at least one is strictly positive (condition (iii))

4. The property of the sign of the derivatives holds because $0 ≤ ρ_r ≤ σ_n < 1$ (condition (ii)).

To show that cross-partial derivatives exhibit the required property, I begin by simplifying the notation. Set $α_{nr} = (1 - σ_n)/(1 - ρ_r)$ and $β_r = 1 - ρ_r$, and note that $α_{nr}, β_r \in [0, 1]$. I can then rewrite $G$ as

$$G = \sum_{r=1}^{N+M} \left( \sum_{n \in B_r} \sum_{j \in S_n} \exp(\frac{1}{1-σ_n}Y_j^{-\sigma_n}) \right)^{α_{nr}} \right)^{β_r} \right).$$

Fix some $k \in \{1, \ldots, J\}$, and let $K = \{i_1, i_2, \ldots, i_k\}$ be a subset of $\{1, \ldots, J\}$ containing $k$ elements. I want to show that

$$\frac{∂^k \tilde{G}}{∂Y_{i_1} \cdots ∂Y_{i_k}}$$

is nonnegative for odd $k$ and nonpositive for even $k$. This is equivalently to showing that:

$$\frac{∂^k \tilde{G}}{∂Y_{i_1} \cdots ∂Y_{i_k}}$$
is nonnegative for odd $k$ and nonpositive for even $k$, where $\bar{Y}_j \equiv \frac{1}{\sigma_n} Y_j$ for every nest $n$ and product $j \in S_n$ and

$$\bar{G} = \sum_{r=1}^{N+M} \left[ \sum_{n=1}^{N} w_{r-n} \left( \sum_{j \in S_n} \bar{Y}_j \right)^{\alpha_n} \right]^{\beta_r}.$$

I focus on the latter condition, and remove the tildes to ease notation.

For every $r$, let

$$H' = \left[ \sum_{n=1}^{N} w_{r-n} \left( \sum_{j \in S_n} Y_j \right)^{\alpha_n} \right]^{\beta_r},$$

and note that $H = \sum_r H'$. Define

$$H'_k \equiv \frac{\partial^k H'}{\partial Y_{i_1} \cdots \partial Y_{i_k}}.$$

It is enough to show that, for every $r$, $H'_k$ is nonnegative for odd $k$ and nonpositive for even $k$. In the following, I fix an $r$, and drop the $r$ index to ease notation. The final object of interest is therefore

$$H = \left[ \sum_{n=1}^{N} v_n \left( \sum_{j \in S_n} Y_j \right)^{\alpha_n} \right]^{\beta} \equiv f(g(Y)),$$

where $v_n = w_{n-r}$; $f(X) = (X)^\beta$; and $g(Y) = \sum_{n=1}^{N} v_n (\sum_{j \in S_n} Y_j)^{\alpha_n}$.

To find the $k$th derivative of the function composition, I apply the multivariate version of the Faà di Bruno formula (Hardy (2006)), and derive the sign of each term in the Faà di Bruno expression:

$$\frac{\partial^k}{\partial Y_{i_1} \cdots \partial Y_{i_k}} H(Y) = \sum_{\pi \in \Pi} f(|\pi|) (Y) \cdot \prod_{B \in \pi} \frac{\partial |B|}{\partial Y_j} g(Y),$$

where $\pi$ runs through the set $\Pi$ of all partitions of the set $\{i_1, \ldots, i_k\}$; $B \in \pi$ means that the variable $B$ runs through the list of all the blocks of the partition $\pi$; $|B|$ denotes the size of the block $B$ and $|\pi|$ is the number of blocks in the partition $\pi$.

I now show that each term in the above sum has the desired sign. Fix some $\pi \in \Pi$.

I distinguish two cases.

Case 1. Suppose the partition $\pi$ is such that there exists $B_0 \in \pi$ such that $\forall n, B_0 \not\subseteq S_n(B)$. Then, clearly, $\prod_{B_0 \in \pi} \frac{\partial |B_0|}{\partial Y_j} g(Y) = 0.$
Case 2. Suppose instead that the partition \( \pi \) is such that, for every \( B \in \pi \), there exists \( n(B) \) such that \( B \subseteq S_{n(B)} \). Then

\[
\begin{align*}
 f(|\pi|)(X) \cdot \prod_{B \in \pi} \frac{\partial^{|B|} g(Y)}{\partial Y_j} \\
= f(|\pi|)(X) \cdot \prod_{B \in \pi} \frac{\partial^{|B|} v_n(B)}{\partial Y_j} \left( \sum_{l \in S_n(B)} Y_l \right)^{\alpha_n(B)} \\
= \prod_{i=0}^{|\pi|-1} (\beta - i) \left( f(X) \right)^{(|\pi| - i)} \cdot \prod_{B \in \pi} (\alpha_n(B) - i) v_n(B) \left( \sum_{l \in S_n} Y_l \right)^{(\alpha_n(B) - |B|)}.
\end{align*}
\]

The sign of equation (6) is either zero or

\[
\text{sgn} \left( f(|\pi|)(X) \cdot \prod_{B \in \pi} \frac{\partial^{|B|} g(Y)}{\partial Y_j} \right) = (-1)^{|\pi|+1} \cdot (-1)^{|\pi|+\sum_{B \in \pi} |B|}
\]

\[
= (-1)^{|\pi|+1+\sum_{B \in \pi} |B|}
\]

\[
= (-1)^{1+i+1}
\]

\[
= (-1)^{1+k}
\]

Therefore

\[
\frac{\partial k}{\partial Y_{i_1} \ldots \partial Y_{i_k}} G(Y) \begin{cases} 
\geq 0 & \text{if } k \text{ is odd,} \\
\leq 0 & \text{if } k \text{ is even.}
\end{cases}
\]

A.2 Decomposition into three logits

According to the GEV postulate, the choice probability of buying product \( j \) is

\[
s_j = e^{\delta_j} \cdot G_j(e^{\delta_1}, \ldots, \delta_j)
\]

where \( G_j = \frac{\partial G}{\partial e^{\delta_j}} \) is the partial derivative of \( G \) with respect to \( e^{\delta_j} \), as derived above.

As \( G \) is defined by equation (2), choice probabilities are therefore

\[
s_j = \frac{e^{\delta_j} \sum_{r=n}^{n+M} (e^{\delta_j})^{\frac{a_r}{1-\rho_r}} \cdot w_{r-n} Z_{r-n}^\rho \cdot D_r^{1-\rho_r}}{\sum_{r=1}^{N+M} (D_r)^{1-\rho_r}}.
\]
I asserted that the product of two conditional and one marginal probabilities in equation (3) equals the joint probability in the above equation (7). I verify the assertion as follows:

\[
s_j = \frac{e^{\delta_j} \sum_{r=n}^{n+M} \left( e^{\delta_j} \frac{\sigma_n}{1-\sigma_n} \cdot w_{r-n} Z_n^{\frac{\rho_r-\eta_n}{1-\rho_r}} \cdot D_r^{-\rho_r} \right)}{\sum_{r=1}^{N+M} (D_r)^{1-\rho_r}}
\]

\[
= \sum_{r=n}^{n+M} \left( \exp\left( \frac{\delta_j}{1-\sigma_n} \right) w_{r-n} \left( \sum_{j \in S_n} \exp\left( \frac{\delta_j}{1-\sigma_n} \right) \right)^{\frac{\rho_r-\eta_n}{1-\rho_r}} \right) - \rho_r
\]

\[
/ \sum_{r=1}^{N+M} \left( \sum_{n \in B_r} \left( \sum_{j \in S_n} \exp\left( \frac{\delta_j}{1-\sigma_n} \right) \right)^{\frac{\rho_r-\eta_n}{1-\rho_r}} \right)^{1-\rho_r}
\]

\[
= \sum_{r=n}^{n+M} \left( \sum_{j \in S_n} \exp\left( \frac{\delta_j}{1-\sigma_n} \right) \right) w_{r-n} \left( \sum_{j \in S_n} \exp\left( \frac{\delta_j}{1-\sigma_n} \right) \right)^{\frac{\rho_r-\eta_n}{1-\rho_r}}
\]

\[
= \sum_{r=n}^{n+M} \left( \sum_{n \in B_r} \left( \sum_{j \in S_n} \exp\left( \frac{\delta_j}{1-\sigma_n} \right) \right)^{\frac{\rho_r-\eta_n}{1-\rho_r}} \right)^{1-\rho_r}
\]

\[
= \sum_{r=n}^{n+M} \exp\left( \frac{\delta_j}{1-\sigma_n} \right) \cdot w_{r-n} Z_n^{\frac{\rho_r-\eta_n}{1-\rho_r}} \cdot \exp((1-\rho_r)I_r) / \sum_{r=1}^{N+M} \exp((1-\rho_s)I_s)
\]

\[
= \sum_{r=n}^{n+M} s(j|n) \cdot s(n|B_r) \cdot s(B_r),
\]
where

\[ Z_n = \sum_{j \in S_n} \exp \left( \frac{\delta_j}{1 - \sigma_n} \right), \]

\[ I_r = \ln \sum_{n \in B_r} w_{r-n} Z_n^{\frac{\lambda - \sigma_n}{1 - \rho_r}}. \]

### A.3 First- and second-order derivatives of the generating function \( G \)

**First derivative**  For \( j \in S_n \), the first cross-derivative \( G_j = \frac{\partial G}{\partial Y_j} \) is:

\[ G_j = \sum_{r=n}^{n+M} Y_{f_j}^{\frac{\sigma_n}{1-\sigma_n}} w_{r-n} Z_n^{\frac{\rho_r - \sigma_n}{1-\rho_r}} D_r^{-\rho_r}, \]

where \( Z_n \) and \( B_r \) are defined as follows:

\[ Z_n = \sum_{j \in S_n} Y_j^{\frac{1}{1-\sigma_n}}, \]

\[ D_r = \sum_{n \in B_r} w_{r-n} \left( \sum_{j \in S_n} Y_j^{\frac{1}{1-\sigma_n}} \right)^{\frac{\lambda - \sigma_n}{1 - \rho_r}}. \]

**Second derivative**  The second cross-derivative \( G_{ji} = \frac{\partial^2 G}{\partial Y_i \partial Y_j} \) is given by

1. for \( i, j \in S_n, i \neq j \),

\[ G_{ji} = \sum_{r=n}^{n+M} \frac{\rho_r}{1 - \rho_r} Y_{f_i}^{\frac{\sigma_n}{1-\sigma_n}} Y_{f_j}^{\frac{\sigma_n}{1-\sigma_n}} w_{r-n} Z_n^{\frac{\rho_r - \sigma_n}{1-\rho_r}} D_r^{-\rho_r}, \]

\[ + \sum_{r=n}^{n+M} \frac{\rho_r - \sigma_n}{(1 - \rho_r)(1 - \sigma_n)} Y_{f_i}^{\frac{\sigma_n}{1-\sigma_n}} Y_{f_j}^{\frac{\sigma_n}{1-\sigma_n}} w_{r-n} Z_n^{\frac{\lambda - \sigma_n}{1-\rho_r}} D_r^{-\rho_r}. \]

2. for \( i, j \notin S_n \), and \( i, j \in B_r, i \neq j \),

\[ G_{ji} = \sum_{r=n(i)}^{n(j)+M} \frac{\rho_r}{1 - \rho_r} Y_{f_i}^{\frac{\sigma_n(i)}{1-\sigma_n(i)}} Y_{f_j}^{\frac{\sigma_n(j)}{1-\sigma_n(j)}} w_{r-n(i)} Z_n^{\frac{\rho_r - \sigma_n(i)}{1-\rho_r}} Z_n^{\frac{\rho_r - \sigma_n(j)}{1-\rho_r}} D_r^{-\rho_r}. \]

3. for \( i, j \notin S_n \), and \( i, j \notin B_r, i \neq j \),

\[ G_{ji} = 0. \]
